Fiscal Policy, Interest Rates, and Output: Equilibrium-Correction Dynamics in the US Economy

Hans-Martin Krolzig & Isaac Sserwanja
School of Economics, University of Kent, Keynes College, Canterbury CT2 7NP
November 2014

Abstract

Joint modelling of fiscal and monetary policies should elucidate on their interaction. We estimate a large parsimonious structural vector equilibrium correction model (PSVECM) to analyse the dynamics of eight variables from the US economy. Shocks to fiscal and monetary variables reveal interesting observations, with the results broadly in agreement with economic theory. A shock to only government spending indicates a government spending multiplier of 1.62. There is also a temporary increase in the cost of borrowing. However, a simultaneous shock to both tax and spending that leaves the deficit unchanged suggests a balanced budget multiplier of 1.77. Increasing the federal funds rate by a percentage point is followed by falling output, inflation, and tax revenues but the change in government spending is insignificant. In addition, the yield on thirty-year maturity corporate bonds rises by 0.32 of a percentage point.

Keywords: Deficit; balanced budget multiplier; spending multiplier; fiscal policy; monetary policy.

JEL classification: E62; E52; E63; G12; H62

1 Introduction

One outcome of the 2007-2008 Global Financial Crisis and the subsequent Great Recession is the re-emergence of fiscal policy as a powerful tool in the economic policy management of major economies around the world. Falling output was followed by falling tax revenues which when coupled with bailing out the financial system explains worsening budget deficits in various countries. Given a global economy that is yet to fully recover, and is characterised by high debt levels, deficits, and unconventional monetary policies including near-zero interest rates, a natural question ought to be asked: how does the budget deficit interact with interest rates? This empirical study answers this question and more through the analysis of US data. Our contribution to the literature is twofold. First, we analyse the interaction between fiscal policy and monetary policy and how they have affected long-maturity bond yields over the last fifty years. Second, we measure fiscal multipliers over the same period, thereby characterising the extent to which fiscal policy affects output. A characteristic of our approach is the emphasis of theoretically-consistent long-run relationships which supports the structural interpretation we attach to our results. For example, we explicitly include the deficit as a cointegration relation to allow us to study the dynamic feedback between this important budget constraint and the rest of the economy. Our results have a Keynesian flavour. From a Keynesian perspective, increasing government spending - spending,
henceforth - or cutting taxes can be used to stimulate aggregate demand. This may be especially necessary during recessions. According to Ilzetzki et al. (2013), fiscal expansion if well-targeted to optimise the fiscal multiplier can stimulate aggregate demand and subsequently take an economy out of a downturn faster than if no intervention were undertaken. In fact, empirical evidence in Feldstein (1982) and Eisner (1992), among others, links budget deficits and output. This is in opposition to the Ricardian equivalence hypothesis in Barro (1989) that budget deficits do not affect output. The deficit-output debate is one with real and potentially long-lasting economic consequences. Alesina & Ardagna (2010) look at fiscal stimuli and adjustments in OECD countries between 1970 and 2007. They find: (1) tax-cut-based fiscal stimuli more likely to increase growth compared to increasing spending, and (2) fiscal adjustment in the form of a cut in spending and no tax increase is more likely to lower the deficit and the debt-to-GDP ratio than one based on a tax increase. Counter arguments posit that fiscal expansion - often entailing an increase in government debt levels - may be necessary to stop a recession from getting worse. It is important to study fiscal and monetary policy simultaneously not least because governments (to an extent) react to changes in their borrowing costs as demonstrated in de Groot et al. (2014). That there is a fiscal reaction to an increase in the interest rate at which the governments borrows can improve budget discipline, de Groot et al. (2014) argues.¹

1.1 Fiscal policy and output

One branch of the fiscal policy literature focusses on its relationship with output. Studies on this often include, among other aspects, estimations of spending and/or tax multipliers. Blanchard & Perotti (2002) combine a structural vector autoregressive (SVAR) modelling and event-study approach to investigate the response of output and its components to tax and spending shocks in the postwar US. Large fiscal events such as the 1975 tax cut are used in the event-study section. Using institutional information and the elasticity of fiscal variables to economic activity to achieve identification, their findings are largely in line with standard Keynesian theory predictions. Positive spending shocks increase private consumption and output. Positive tax shocks have a negative effect on output. Increasing spending or taxes reduces investment spending by the private sector. Afonso & Souza (2012) look at US data 1970(3)-2007(4) and include the government inter-temporal budget constraint in modelling the macroeconomic effects of fiscal policy. They include the response of fiscal variables to government debt dynamics. The observed response is also Keynesian in nature. A positive spending shock has a positive but small effect on gross domestic product (GDP) dynamics, private consumption, private investment, and asset markets. Stock prices react quickly to fiscal policy shocks but house prices react more persistently. When the shock is to revenue, a crowding-out effect is detected as a positive response in private investment is quickly eroded. It is claimed that taking debt dynamics into account makes GDP and long-term interest rates more responsive, in addition to more persistent fiscal policy effects. Rossi & Zubairy (2011) finds fiscal shocks are more relevant in explaining output fluctuations in the medium term while monetary shocks are associated more with business cycle fluctuations. The approach in Rossi & Zubairy (2011) is interesting in that it simultaneously studies fiscal and monetary shocks on the macroeconomy. We too take this approach to jointly model fiscal and monetary policy, justified by the idea that the two policies can

¹Markets do not however impose 'budgetary discipline', at least in a timely manner, as was evident when for several years the rates at which some peripheral eurozone countries was markedly lower given their budget positions. de Groot et al. (2014) argue for fiscal rules to complement markets as an enforcer of fiscal sustainability.
(indirectly) interact via their effects on common variables. This is certainly the case for the US where monetary policy has low unemployment as one of its goals while at the same time government-run fiscal policies do affect the level of unemployment.

Favero (2002) jointly models monetary and fiscal policy in Germany, France, Italy, and Spain, observing that not jointly modelling the two policies causes some estimated parameters to be insignificant and ignores important interactions between the two. Favero (2002) finds (1) 1970s monetary policy by non-German authorities was not able to stabilise inflation. Inflation stabilisation was achieved in the 1980s and 1990s when domestic monetary policy was tied to German monetary policy, (2) stable inflation has been achieved despite a lack of fiscal discipline, and (3) the interaction between fiscal and monetary authorities depends on the response spending and taxes to interest payments on public debt. Afonso & Souza (2011) focusses on the link between fiscal policy and asset markets for the US, UK, Germany, and Italy. Fiscal shocks are identified following Blanchard & Perotti (2002) above. Like Favero & Givazzi (2008), the specification in Afonso & Souza (2011) includes a government debt variable to capture effect of debt dynamics feedback on fiscal policy. For the US, spending shocks have a positive and persistent effect on house prices but a negative effect on stock prices. Shocks to government revenues have a negative impact on house prices, and a small but positive impact on stock prices. In fact, fiscal policy shocks only have a minor effect on the behaviour of stock markets and house prices. Perotti (2004) studies fiscal policy effects in the US, West Germany, the UK, Canada, and Australia, finding spending and tax cut effects on GDP and its components weakened after 1980. While relatively large positive effects are observed for private consumption, there is no response from private investment. Fatas & Mihov (2001) finds that consumption and employment increase in response to increases in spending.

One way to analyse fiscal policy effects is by measuring fiscal multipliers. The spending multiplier tells us how much output increases by when spending goes up. Consensus among economists on the size of fiscal multipliers is elusive. Part of the disagreement can be attributed to how fiscal shocks are identified and whether the researcher takes a Keynesian or classical view. Ricco (2014) argues that ignoring policy anticipation effects and and assuming perfect information results in wrong estimations of fiscal multipliers. Estimate of the spending multiplier lie between 0.5 and 2.5 according to Chinn (2013). On whether fiscal multipliers are dependent on prevailing economic conditions, Ramey & Zubairy (2014) do not find evidence that spending multipliers are different based on slack in the economic system. In fact, they argue that "spending multipliers were not necessarily higher than average during the Great Recession" when interest rates were near zero. Some recent studies on fiscal multipliers during recessions include but are not limited to Auerbach & Gorodnichenko (2013), Auerbach & Gorodnichenko (2012), Bachmann & Sims (2012). Fatas & Mihov (2001) finds a spending multiplier of more than one, driven by an increase in private consumption. The response of investment to spending is insignificant. Auerbach & Gorodnichenko (2012) analyse fiscal multiplier variability over the business cycle. Using regime-switching models, fiscal multipliers are found to be larger during recessions than in expansions. Their analysis of disaggregated spending components finds military spending to have the largest multiplier. They also find that taking into account the predictability of fiscal policy increases multipliers in recessions. Perotti (2004) finds a US spending multiplier of more than one based on pre-1980 data.
1.2 Fiscal policy and interest rates

There are mixed results on the interaction between fiscal policy and interest rates, as are the variety of methodologies employed. Event studies, SVARs, and combinations of the two are quite popular. Owing to the approach in this paper, the VAR literature commands the most attention here which should allow for a clearer comparison of results. Often, bonds are investigated in the paradigm of monetary policy. However, unprecedented government intervention in the economy in response to the Great Recession has made fiscal policy a much more active component of economic policy making, necessitating analysis of the interaction between long-maturity bond yields and fiscal policy. We include the federal funds rate to represent monetary policy. In a way, we are heeding the caution in Rossi & Zubairy (2011) that ignoring that "both monetary and fiscal policy shocks simultaneously affect macroeconomic variables incorrectly attributes some macroeconomic fluctuations to the wrong source." Favero & Givazzi (2008) analyse the impact of fiscal shocks while allowing the level of public debt to affect the debt service cost, tax, and spending. They argue that "omitting such a feedback can result in incorrect estimates of the dynamic effects of fiscal shocks." They explain the absence of fiscal shock effects on long-term interest rates (ltir) as due to misspecified VARs that exclude a debt feedback, in addition to not endogenising debt dynamics. The level of debt-to-GDP ratio, they argue, impacts ltir.

Marattin et al. (2011) uses cointegration to study the impact of fiscal shocks on government debt and ltir in the US, Germany, and Italy for the 1983-2009 period. Using the common trends methodology to distinguish transitory shocks (financial and inflationary) from permanent shocks (fiscal and monetary) they find (1) debt accumulation is followed by higher ltir for Germany and Italy but not for the US. The reaction of ltir in the US explained by liquidity effects. (2) Fiscal shocks determine both permanent and cyclical components of the ltir. Debt shocks have asymmetric effects depending on debt/GDP levels for Italy, and Germany but not the US. Laubach (2011) studies fiscal variables and interest rates under two scenarios: under heightened levels of sovereign default risk and, when the risk that the government will default on its debt obligations is of no concern to creditors. Again, under normal default risk conditions, results are Keynesian. Contractionary fiscal policy results in lower interest rates, real economic activity, and prices as the Federal Reserve responds with a cut in (short-term) rates. However, a weak economic environment leads to a decline in the surplus/GDP ratio, and a subsequent increase in the debt/GDP ratio. Laubach (2009) looks at links between projected deficits and public debt on one hand and long-horizon forward rates. Deficit and debt effects on interest rates are significant, both statistically and economically, with parameter estimates that are consistent with the neo-classical growth model. It is claimed that the effects of deficit and (public) debt projections by the Congressional Budgetary Office (CBO) in the US are evident at the longer end of the yield curve. A percentage point increase in the projected deficit-to-GDP (debt-to-GDP) ratio results in interest rates rising by 25 (3 to 4) basis points. Gale & Orszag (2003) give a broad review of the literature on fiscal policy and interest rates. They suggest that studies that incorporate expected deficits tend to find a link between deficits and interest rates. They argue that deficits may increase nominal interest rates because (1) they reduce aggregate savings if foreign capital inflows and domestic private savings rises are insufficient to compensate for the fall in public saving, and (2) they lead to an increase in the stock of public debt. A higher outstanding amount of government bonds commands a higher interest rate as investors demand higher a premium to hold additional government bonds as opposed to other financial assets. Also, expected future deficits have significant effects
on long-term bond yields. They also emphasise the negative long-term effect of deficits on the economy especially via reduced national saving rates that result in lower national income. In analysis of financial variables behaviour around periods of major changes in the fiscal stance in OECD countries for the period 1960-2002, Ardagna (2009) finds that long-term government bond yields fall in periods of budget consolidation but rise during fiscal deterioration. Where the fiscal policy is associated with a permanent reduction in public debt, there is a strong effect on long-term government bond yields. Stock markets surge as a result of fiscal adjustments involving expenditure reductions but fall during fiscal expansions. Importantly, these results depend on prevailing fiscal conditions and the type of fiscal policy: a spending cut that permanently reduces government debt during high-deficit periods is associated with bigger falls in interest rates.

Engen & Hubbard (2004) analyse the effect of federal government debt and interest rates. Owing to the dependence of results on model specifications, they use various specification on the same data set. They conclude that an increase in debt of 1% of GDP, ceteris paribus, increases the real interest rate by about 0.03%. In a discussion of a trend in the interest rate and its drivers, Brook (2003) identifies cyclical and portfolio factors as the main drivers of the 2000-2003 fall in real long-term interest rates. For selected European countries, falling inflation and exchange rates could also have lowered the equilibrium real interest rate. Attention is also drawn to US evidence pointing to a causal link from fiscal variables to real interest rate. This link is characterised by both the actual and projected fiscal fiscal positions, underlining the importance of ‘expectations’ in this relationship. Further, an international dimension is also explored, with US originated shocks having a noteworthy effect on European and Japanese bonds than vice versa. Over all, the general picture from the literature is in agreement with the findings of this paper which are in line with the traditional Keynesian view that expansionary fiscal policy has a positive impact on output.

2 Theoretical framework

The IS-LM model provides a viable framework to explore the interaction between budget deficits and and real output. The Keynesian model posits that fiscal policy influences economic activity by affecting aggregate demand. If there are under-utilised resources in the economy, for example during a recession, then increasing the budget deficit - tax cuts, increased spending, or a combination of the two - should put upward pressure on aggregate demand. As aggregate demand expands via the fiscal multiplier, output increases. Expansionary fiscal policy shifts the IS curve to the right such that the IS and LM schedules intersect at a new equilibrium with higher output and interest rates. The higher interest rate level offsets some of the multiplier effects by crowding out private investment.

2.1 Multipliers

We consider the spending multiplier and the balanced budget multiplier. The spending multiplier gives the change in GDP due to a change in spending. The balanced budget multiplier gives the change in GDP due to a simultaneous change in spending and tax that leaves the deficit unchanged.\(^{2}\) If both

\(^2\)Early advances on the balanced budget multiplier - also known as the Havelmo theorem - were by Gelting (1941) and Trygve Haavelmo in 1945.
spending and revenue change by the same amount, the Haavelmo theorem posits that national income will also change by the same amount, suggesting a multiplier of one. Matthiessen (1966) questioned the validity of the 1:1 multiplier, while still claiming it to be non-zero. This is in contrast to a deficit-spending multiplier which is greater than one. Assuming a closed economy and defining a goods market equilibrium with a Keynesian consumption function and autonomous investment spending as

\[ Y = I + \bar{C} + c(Y - T) + G \]  

such that effective demand is

\[ Y = \frac{I + \bar{C} - cT + G}{1 - c} \]  

Then under a deficit spending shock, we have \( \Delta T = 0 \) such that the (Keynesian) multiplier \( M = \frac{dY}{dG} \).

For a tax-financed shock (Haavelmo theorem), \( \Delta T = \Delta G \) and \( M = \frac{dY}{dG} = 1 \).

Our model is formulated in logs with \( y = \log Y \), \( g = \log G \), \( \tau = \log T \) so for the multiplier as an elasticity we have (1) under deficit spending (\( \Delta T = 0 \)):

\[ \mu(0) = 1 \]

and (2) for the tax-financed spending \( dT = dG \) (‘Haavelmo Theorem’)

\[ \mu(0) = 1 \]

One can also consider the dynamic multiplier, derived by including the Robertson lag in the consumption function: \( C_t = \bar{C} + c(Y_{t-1} - T_{t-1}) \)

\[ M_t(h) = \frac{\sum_{i=0}^{h} dY_{t+i}}{\sum_{i=0}^{h} dG_{t+i}} = \frac{\sum_{i=0}^{h} Y_{t+i} dY_{t+i}}{\sum_{i=0}^{h} G_{t+i} dG_{t+i}} \approx \frac{G/Y}{Y-1} \mu(h) = \frac{G/Y}{Y-1} \sum_{i=0}^{h} dY_{t+i} \]

where \( dY_{t+h} \) and \( dG_{t+h} \) denote the responses to a fiscal shock \( h \) quarters ago.

3 Data

The aim of this paper is to estimate the size of the fiscal multiplier for the post-war US economy using a large parsimonious structural vector equilibrium correction model (PSVECM). We collect quarterly data
on the US economy for the 1960(1)-2013(4) period, with the sample size dictated by data availability. The data include GDP, government spending, net taxes, inflation expectations, the GDP deflator, the personal consumption expenditures (PCE) price index,\(^3\) the federal funds rate (ffr), the 30-year maturity government bond yield, and the 30-year maturity Moody’s Baa-rated corporate bond yield. Table 1 and equations (9) and (10) give data details and transformations characterising our 8-dimensional system.

FG stands for federal government while SLG is state and local government. The number in parentheses correspond to tax and spending component lines in National Income and Product Accounts (NIPA) tables 3.1, 3.2 and 3.3. The data cover total government (federal, state and local governments) and were downloaded from the Bureau of Economic Analysis (BEA) website on 25 June 2014.

\[ \text{Net taxes} = \text{personal current taxes } FG(3) + \text{taxes on production and imports } FG(4) + \text{taxes on corporate income } FG(7) + \text{taxes from the rest of the world } FG(10) + \text{contributions for government social insurance } FG(11) + \text{income receipts on assets } FG(12) + \text{current transfer receipts } FG(16) - \text{current transfer payments to persons } FG(24) - \text{interest payments } FG(29) + \text{personal current taxes } SLG(3) + \text{taxes on production and imports } SLG(6) + \text{taxes on corporate income } SLG(10) + \text{contributions for government social insurance } SLG(11) + \text{income receipts on assets } SLG(12) + \text{current transfer receipts } SLG(16) - \text{federal grants – in – aid } SLG(17) - \text{government social benefit payments to persons } SLG(23) - \text{interest payments } SLG(24) \]

\(^3\)Inflation expectations’ is a survey-based measure that moves more closely with consumption-based price indices than with the GDP deflator. To exploit this potential long-run relation, we use the PCE index to calculate inflation while the GDP deflator is retained to deflate GDP, net taxes, and spending.
Government spending  =  consumption expenditures (16) + gross government investment (34)

(10)

3.1 Output, net taxes, and government spending

We define net tax and spending in the spirit of Blanchard & Perotti (2002). This should allow for comparing of results with this widely cited study on US fiscal policy. Net taxes are defined as the sum of tax and non-tax receipts, contributions for government social insurance less net transfer payments and net interest payments. We use net tax as opposed to gross tax because we are interested in the government budget constraint. Taking gross tax would ignore the fact that part of the current receipts have to be spent on prior commitments such as interest payments and social security transfers. Government spending is defined as consumption expenditures and gross government investment.

3.1.1 Our fiscal variables versus those in Blanchard & Perotti (2002)

The literature on US fiscal policy from the last decade extensively cites the Blanchard & Perotti (2002) study, making it a good benchmark to compare our results. They too work with total government data, defining net taxes as "the sum of Personal Tax and Non-tax Receipts, Corporate Profits Tax Receipts, Indirect Business Tax and Nontax Accruals, and Contributions for Social Insurance, less Net Transfer Payments to Persons and Net Interest Paid by Government. Government spending is Purchases of Goods and Services, both current and capital." While Blanchard & Perotti (2002) motivate equations (9) and (10), the two sets of series differ slightly. This difference is inevitable, given the numerous data revisions, and component re-classifications that NIPA tables have undergone over the last twelve years.4

Figure 1 compares the fiscal series in this study against those in Blanchard & Perotti (2002). For the period over which the two samples overlap, we can see from the top right graph that spending in both studies are almost identical. This view is further supported by their difference plot in the bottom graph. It appears that our spending variable is just a level shift up. Differences in tax are more pronounced, with a level shift downwards in our tax measure obvious in the top left and bottom right graphs. This level shift between the two data sets is also clear in the deficit plots given by the lower left graph. These differences notwithstanding, we believe that our tax and spending definitions approximate well those in Blanchard & Perotti (2002), as is evident in figure 1 and table 2.

3.2 Inflation

Inflation is represented by the forward-looking inflation expectations measure from the Survey of Consumers run by the University of Michigan/Reuters and an actual inflation measure from the PCE price index. Inflation expectations are included to capture agent expectations of the path of prices in the economy and to reduce the 'price puzzle' problem common in VAR analysis. This puzzle involves a price

4Blanchard & Perotti (2002) takes 'federal corporate profits tax' data from the Quarterly Treasury Bulletin. Our fiscal data are solely from the NIPA.
rise in response to tightening monetary policy, such as an increase in the ffr. According to figure 2, the relationship between these two measures appears stable over time, making them viable candidates for a cointegration relation. This is supported by the result in table 6 where $\pi - \pi^e$ is $I(0)$.

### 3.3 Interest rates

The three interest rates represent the financial sector with the federal funds rate as the monetary policy proxy. The Treasury bond yield is the cost of borrowing for thirty years by the government. The

corporate bond yield represents the average interest rate faced by firms when they issue debt maturing in thirty years time. Treasury bond yield data is only available from February 1977 and is also missing between 2002M3 and 2006M1, a period during which no thirty-year maturity Treasuries were issued by the government. We use splicing (details in appendix A) together with the twenty-year maturity bond yield to approximate the missing data. All interest rate series plots are given in figure 3.

Figure 3  The federal funds rate, the government bond yield, and the corporate bond yield.

3.4  Descriptive statistics and unit roots

Table 3 summarises the statistics while unit root test profiles of variables are in tables 4, 5, and 6. Only the log of the tax-to-GDP ratio appears to be I(0). All the other variables are I(1) and so have to be differenced once to make them stationary. We also test for unit roots on a selection of economic
theory-inspired relations. This serves as a preliminary check on the (expected) stationarity of prospective cointegration relations. They include: (i) the deficit \((\tau - g)_t\), (ii) the term structure of interest rates \((r - i)_t\), (iii) the risk premium \((b - r)_t\), (iv) the actual-expected inflation difference \((\pi^e - \pi)_t\), and (v) the real short-term interest rate \((i - \pi)_t\). They are all \(I(0)\) as expected. That the deficit and \((\tau - y)_t\) are \(I(0)\) while \((g - y)_t\) is \(I(1)\) is a contradiction because it implies that an \(I(0)\) variable cointegrates with an \(I(1)\) variable. However, at this stage it is helpful to keep in mind that unit root tests are only suggestive and not definitive given their low power. Furthermore, \((\tau - y)_t\) actually has a unit root \((p\text{-value } 0.013)\) if the test is specified with 0 lags as selected by the Schwarz information criteria (SIC).

Also, the ADF finds the deficit to be \(I(0)\) regardless of whether the test lags are chosen based on the Akaike, Schwarz or Hannan-Quinn criteria. Impulse response analysis will confirm that after a shock, the deficit is only ever temporarily away from equilibrium.

**4 The modelling process**

We estimate a structural vector error-correction model (SVECM) and use it to analyse the dynamics of eight key US economic variables spanning more than fifty years. The modelling procedure is general-to-specific. We start with an unrestricted VAR\(p\) model and determine the lag length \(p\). We then determine the number cointegrating relations in the system the trace test from Johansen (1988) and Johansen (1995). These are linear relations among (some, or all of) the series that are stable in the long-run. Next, we apply the PC algorithm from Pearl (2000) and Spirtes et al. (2000) to the residuals from the identified cointegrated VAR to retrieve the contemporaneous relationships structure among the variables. By mapping this contemporaneous structure into the VECM, we estimate the structural VECM. The SVECM still has several insignificant parameters at this stage. We therefore use the Gets reduction procedure in Krolzig (2003) to drop insignificant terms, leaving behind a parsimonious structural model (PSVECM) that is a congruent representation of the data generating process (DGP). It is with this PSVECM that we implement economic analysis. We carry out impulse response analysis to understand how shocks propagate the system.

\(^5\)However, the Hannan-Quinn criterion (HQ) selects 4 lags and \((\tau - y)_t\) is \(I(0)\) according to a 0.013 p-value, in line with the Akaike information criteria (AIC) benchmark test specification. \((g - y)_t\) is \(I(0)\), regardless of the information criteria used in the test specification.
We need the correct lag length processes each with zero mean and trend-coefficients, movement amongst (some of) the variables. If these co-movements are linear and stable, they could run. Looking at the time series plots of our eight variables in figures 2, and 3, there is strong co-

Cointegration analysis aims to identify any linear relationships in the data that are stable in the long-

4.2 Cointegration

We start by estimating the unrestricted 8-dimensional reduced-form V AR(4) model in (11). \( x_t = (y_t, \tau_t, g_t, \pi_t, \pi_t, i_t, r_t, b_t)' \), \( \mu \) is the vector of intercepts and has dimension 8 \( \times \) 1, \( \gamma \) is the 8 \( \times \) 1 vector of trend-coefficients, \( A_j \) an 8 \( \times \) 8 matrix of coefficients at the \( j^{th} \) lag. \( u_t \) is a Gaussian vector of white noise processes each with zero mean and \( \Sigma \) their variance-covariance matrix.

\[
\begin{align*}
x_t = \mu + \gamma t + \sum_{j=1}^{p} A_j x_{t-j} + u_t, \quad u_t \sim \text{NID}(0, \Sigma)
\end{align*}
\]  

We need the correct lag length \( p \) to estimate (11) and of course, the resulting model should pass the usual diagnostic tests, including having autocorrelation-free residuals. The four starting lags are motivated by a need to be consistent with the vast majority of the literature on fiscal and monetary shocks. This choice is also based on the fact that we are working with quarterly data. To check whether the lag length can be reduced, we use various information criteria in table 7. Clearly, the criteria do not agree on one, three, or four lags. But the choice of four lags is within the general-to-specific spirit since any insignificant terms will be dropped in the final model. We therefore choose four lags as indicated by the LR test.

4.2 Cointegration

Cointegration analysis aims to identify any linear relationships in the data that are stable in the long-

Sample: 1960(1)-2013(4). Tests based on \( \Delta x_t = \mu + \gamma t + \beta x_{t-1} + \sum_{j=1}^{p} \phi_j \Delta x_{t-j} + \epsilon_t \) with the lag length selected by the Akaike Information Criteria (AIC). The null hypothesis, \( H_0: \beta = 0 \), implies presence of a unit root and is rejected when t-adjf < CV.
represent cointegration relations. This is supported by results in tables 4 and 6 showing that while all but the \((\tau - y)\) variable are \(I(1)\) in levels, some linear combinations of these variables do produce \(I(0)\) relations. Potential cointegrating relations include: the deficit, the term structure of interest rates, the risk premium, the expected-actual inflation relation, and the real short-term interest rate. A formal test to determine the number of cointegrating relations is given in table 8. The Johansen trace test, Johansen (1988), is based on (12), which is just the error-correction form of (11) less \(\Delta x_{t-j}\) lags. The number of cointegrating relations is given by the rank of matrix \(\Pi\), where \(\Pi = \alpha\beta'\) in (12).

\[
\Delta x_t = \mu + \alpha(\gamma t + \beta' x_{t-1}) + u_t, \quad u_t \sim \text{NID}(0, \Sigma)
\]

Results in table 8 show that at the benchmark 5% significance level, there are four cointegrating relations in the data. It is vital at this stage that the correct number of cointegrating relations is determined, given its importance to proceeding analysis. One runs the risk of making wrong inference if more relations specified than exist in the data. On the other hand, specifying less relations than exist means excluding important information from the analysis, especially in a long-run dynamics study like ours. To this effect, a careful interpretation of the trace test results is warranted. At the traditional 5% significance level, the trace test in table 8 rejects \(H_0: \text{rank}(\Pi) \leq r,\) for \(r = 1, 2,\) or \(3,\) but not \(r \leq 4,\) which is not rejected with 0.073 probability, thereby suggesting four cointegration relations in the data. However, we argue that there are five cointegration relations based on the following reasons. First, results in table 6 suggest a rank of 5, possibly involving relations: \{\((\tau - g),(\tau - y),(r - i),(b - r),(\pi^*-\pi),\) and \((i - \pi)\}\}. Relations 2-5 were identified in Krolzig & Sserwanja (2014a). Second, if relation 1 is the deficit, then it can be justified from economic theory as a binding budget constraint for the government. There is empirical evidence, notably Bohn (1998) and Blanchard & Perotti (2002) among others, that the deficit is indeed stationary, albeit at only the 5% significance level. Finally, while a looser criteria for rejecting \(r = 4, 7.3%\) is still less than 10%, a threshold that is sometimes used in the literature. Certainly, the 18.4% p-value on which the rank of 5 is based is a stronger criteria. We can therefore be reasonably confident that there are 5 linear and stable long-run relations in the data. The five cointegrating relations

indeed suffice to identify the long-run with a 0.1959 joint p-value.

4.3 Contemporaneous relationships between variables

There are various ways to identify monetary and fiscal policy shocks as discussed in Perotti (2007). These are often motivated by what the researcher assumes to be the correct transmission mechanism of the policy in question. Choleski decomposition is a popular identification technique. However, this approach is criticised for assuming the causality direction. It ignores agents who anticipate policy changes and alter their actions accordingly. Misidentifying shocks this way could therefore lead to under-estimation of fiscal multipliers, as pointed out in Ricco (2014). One solution to the 'lack-of-anticipation' critique levelled at traditional identification procedures is the 'narrative' approach in Ramey & Shapiro (1998), Edelberg et al. (1999), Burnside et al. (2004), Romer & Romer (2010), Ramey (2011) and in part, Blanchard & Perotti (2002), among others. This route often involves pinpointing particular

---

6This involves constructing a lower-triangular matrix of contemporaneous causal effects. The implication is that a shock to variable one is instantaneously transmitted to all the other variables, a shock to variable two is transmitted to all other variables but only with a lag to variable one, and so on. A criticism of this approach is it depends on the researcher to determine which shock effects are immediate and which act with a lag. Fatas & Mihov (2001) discusses fiscal shocks identified by Choleski decomposition.

7The ‘event-study’ methodology was developed in Romer & Romer (1989) to analyse monetary policy.

*Test has a restricted trend and unrestricted constant.

Times in history when tax or spending policy changed but not in response to the prevailing state of the economy. These could be increased spending to finance a war or an unanticipated increase in taxes. These shocks are therefore deemed exogenous. Imposing sign restrictions on impulse responses as in Mountford & Uhlig (2009) is another route to shock identification.

How we identify shocks in this study is motivated by the need to let the data speak. Furthermore, our data-driven identification produces a SVECM that is a valid reduction of a Choleski-identified system since the imposed restrictions pass the likelihood ratio test. To this effect, we use the conservative version of PC (CPC) algorithm implemented in the TETRAD software project at Carnegie Mellon University. Details on how this algorithm is used in economics to determine the contemporaneous causal order in SVAR analysis are in Demiralp & Hoover (2003). Spirtes & Glymour (1991), Spirtes et al. (2010), Pearl (2000), and Spirtes et al. (2000) provide further information on this algorithm and its roots in philosophy and computer science. Briefly, it is a graph-theory-based technique that can take as input covariance matrix data and output a directed acyclic graph (DAG) representing the contemporaneous causal pattern in the data generating process. It determines the causal structure among variables by analysing their conditional independence based on tests of conditional correlation.  

We use as input for the algorithm the residuals from the VECM(3) after identifying the long-run structure. The significance level for the dependence test is set to 10%. The graph below gives the causal pattern found by the algorithm. In all, there 8 significant within-quarter interactions among the variables. However, only half of these are oriented with the algorithm unable to orient the remaining 4. These have to be oriented via other means.

---

8If $r_{ij}$ is the unconditional correlation coefficient between variables $i$ and $j$, then the correlation of $i$ and $j$ conditional on $k$ is $r_{ijk} = (r_{ij} - r_{ik}r_{jk})/(\sqrt{1 - r_{ik}^2}\sqrt{1 - r_{jk}^2})$. The significance of the correlation coefficient is determined using Fisher’s $z$-statistic with $H_0: r_{ijk} = 0$ and $z = \ln((1 + r_{ijk})/(1 - r_{ijk})) \sim N(0, 1/(T - 3))$

9Page 89 of the TETRAD manual (version 5.1.0-3) suggests a 5% significance level for dependence for samples of less than 500 observations. With 211 observations, we should use a 5% significance level. However, the SVECM resulting from $\alpha = 5\%$ fails the likelihood ratio test against one identified by Choleski decomposition. Setting $\alpha = 10\%$ gives an SVECM that passes the LR test.
We orient the remaining four links by analysing the 12 model permutations that result from the non-oriented interactions. Ahe Akaike (AIC), Hannan-Quinn (HQ), and Schwarz (SC) information criteria all choose model 5. However, the long-run (Π) matrix for PSVECM5 has a positive eigenvalue, suggesting instability in system defined by causal order 5. This instability is actually apparent in explosive impulse responses from this model. On the other hand, Model 6, despite not being preferred by any of the likelihood-based model ranking measures, generates five eigenvalues lying in the (-1, 0) interval and 3 zero eigenvalues. This is what is expected according to the five cointegrating relations identified earlier. In fact, model 6 impulse response functions are quite reasonable. Further, Model 6 falls within the 5-8 range of models that are theoretically consistent. We therefore map the causal structure underlying model 6 into matrix $B^r$ and estimate the PSVECM.

5.1 Model dynamics

We have estimated a parsimonious structural model (PSVECM) to analyse interaction between fiscal policy and interest rates regarding their effect on output. Misspecification tests in table 10 reveal that some of the model residuals are heteroscedastic. However, our model passes most of the usual diagnostic tests. Critically, all equations pass the autocorrelation test (up to 4\textsuperscript{th} order). Also, none suffers ARCH effects. The RESET test is also passed although the tax equation only passes at the lower 1\% threshold. The few violations notwithstanding, our model seems satisfactory for use in analysis.

\(j\) depends on the number of lags in a particular equation. * indicates test failure at 5\% significance level.

Most coefficients are theoretically-consistent, especially those on long-run relations which are our main interest. The deficit has a negative effect on real GDP. By re-stating part of equation (15): \(ln(Y/D)_t = −0.0079 * ln(G/T)_{t−1} + 0.0017 * (r−i)_{t−1} + 0.21 * ln(G/D)_t + ...\) where D is the GDP deflator, we see that a 1\% increase in \(G/T\) is followed by a 0.0079\% fall in real GDP, ceteris paribus. While statistically significant, this magnitude of arguably of no economic relevance. On the other hand, increasing the liquidity premium by a percentage point elicits a 0.17\% rise in real output. After spending rises by 1\%, GDP increases by 0.21\% contemporaneously. This is an interest result because 0.21\% is also the average ratio of spending-to-GDP for the US economy. Equation (16) suggests taxes are highly endogenous, reacting to four out of five cointegration relations. Taxes are error-correcting via the deficit with a 1\% increase in \(G/T\) leading to a 0.042\% rise in real tax: 100 * \(ln(T/D)_t = 0.042 * 100 * ln(G/T)_{t−1} − 0.45 * (r−i)_{t−1} − 2.4 * (b−r)_{t−1} + 0.57 * (\pi − \pi^*)_{t−1} + ...\) In other words, an increase in the deficit if followed by a tax rise. The liquidity premium has a negative effect on taxes, which is surprising since a positive liquidity premium indicates expected increase in economic activity, and therefore an increase in tax collections. One explanation of the sign is that inflation from a relatively higher government bond causes the real tax fall. A rise in \((b−r)\), which tends to widen during periods of low economic activity, leads to
lower taxes. Combining long-run effects from the liquidity and risk premia, we infer that the government bond yield has a positive effect on tax. For the final cointegration relation effect, inflation expectations above inflation by a percentage point leads real taxes fall by 0.57%. Short-run effects are dominated by output and some dummies. Dummies $\Delta i_{1975}(2)$ and $i_{2008}(2)$ capture the 1975 (temporary) tax cut and the 2007-08 tax rebate. $i_{2013}(1)$ and $\Delta i_{2013}(2)$ are likely due to effects from expiration of the Bush tax cuts of 2001 and 2003.\(^{10}\) Spending is also error-correcting via the deficit. Interestingly, the deficit is the only long-run relation affecting spending. At a speed of 1.6% per quarter, spending adjusts slower than tax (4% adjustment speed per quarter) to maintain the stationary relationship.

Equations (17) and (18) describe inflation dynamics in the system. Both expected inflation and actual inflation error-correct, with the later adjusting about four times faster (63%) than the former (15%) per quarter. Krolzig & Sserwanja (2014a) finds a comparable quarterly adjustment speed of 16% for inflation expectations. The Federal Reserve’s preference and targeting of low, stable inflation since the early 1980s has probably anchored inflation expectations and created a high degree of hysteresis in this variable. Actual inflation, on the other hand, is more likely to be driven by economic fundamentals and so will change as they do. The risk premium is another long-run relation affecting both inflation measures, but differently. During recessions when inflation expectations are low, the risk premium rises as investors move from riskier financial assets and into safer government bonds. However, in an expansion actual inflation rises and as investors move into equities, corporate bond yields rise relative to government bond yields. Dummies $i_{2008}(2)$ and $i_{2008}(4)$ are quite notable because they likely capture the 2008 oil price shock and the financial crisis and Great Recession that took hold in late 2008. Oil prices rose steeply around the summer of 2008.

Equations (19), (20), and (21) represent the financial market. As the monetary policy equation, (21) has a Taylor Rule effect in the interaction between the federal funds rate and the $(\pi - \pi^e)$ relation. Interaction with the liquidity premium captures the expectations hypothesis of the term structure of interest rates. Interestingly, the federal funds rate is sensitive to the deficit. Monetary policy is clearly accommodative by over 30 basis points during recessions which is when the deficit tends to rise. The bond equations are both error-correction via the risk premium, with the Treasury bond doing so at a faster speed. In addition, they are both sensitive to the real interest rate, especially the corporate bond. So, restrictive monetary policy can act through the real short-term interest rate to stabilize long-term interest rates, and therefore inflation. Over all, fiscal and monetary variables interact both in the short and long-run. This interaction is both direct - such as the $(r - i)$ effect in the tax equation - as well as indirectly through other variables.

### 5.1.1 A balanced budget shock

We now look at system impulse responses over a ten year period following Hall (1992). Confidence intervals are also included, constructed via bootstrap with 5000 replications. In addition to spending only or tax only shocks, we are also interested in the effect of a simultaneous shock to both fiscal variables. As mentioned above, where this is done such that the deficit remains unchanged, we have a

\(^{10}\)The ‘Economic Growth and Tax Relief Reconciliation Act of 2001’ and the ‘Jobs and Growth Tax Relief Reconciliation Act of 2003’ also known as the ‘Bush tax cuts’ expired. The highest marginal tax rate also increased from 35% to 39.5%.
balanced budget shock, otherwise known as the Haavelmo theorem. Such an exercise contributes to the on-going public discussion on how to stimulate the economy: changing spending, taxes, or a mixture of the two. The Haavelmo shock requires that \( T \Delta \tau = G \Delta g \), where for \( T \) and \( G \) we use the respective sample means \( \bar{T} \) and \( \bar{G} \). This reduces to \( \Delta \tau = 1.63 \Delta g \). Figure 4 is for impulse responses to a Haavelmo shock. GDP, tax, and spending all rise significantly over the next 10 years. However, there is no change of economic significance in inflation. There is a temporary increase in the Treasury yield relative to the ffr. This steepening in the yield curve is seen reaction of the liquidity premium in figure 5 which, as expected, has all changes in long-run relations as temporary. The deficit is notable for it takes nearly 15 years to return to its long-run path.

**Figure 4**  Level variable response to a tax-financed spending shock

**Figure 5**  Long-run relation response to a tax-financed spending shock
5.1.2 Impulse responses to a spending shock

We also investigate the effects of a spending shock in figures 6 and 7. After spending goes up by 1%, output rises by 0.21% on impact. The rises in output, tax, and spending are all still significant ten years after the initial shock. The responses of inflation and interest rates are similar to those after a Haavelmo shock, suggesting that the spending component dominates the tax component in the Haavelmo shock. According to figure 7, deficit spending stimulates the economy to the extent that it reduces the risk premium and the real short-term interest rate, albeit temporarily. The (temporary) increase in the liquidity premium also points to the spending shock having a stimulating effect on economic activity.

We also estimate the dynamic multiplier at several horizons for both the deficit spending and the tax-funded spending shocks. The $X$-variable dynamic multiplier, $M_X^X(h)$, is defined as the change in GDP $h$ quarters after a unit change in $X$. This is given by $M_X^X(h) = \frac{\Delta Y_{t+h}}{\Delta X_{t+h}} = \left( Y \frac{\sum dY_{t+h}}{\sum dx_{t+h}} \right) \approx \left( \bar{Y} \frac{\sum dY_{t+h}}{\sum dx_{t+h}} \right)$, where $dx_{t+h}$ and $dY_{t+h}$ denote responses to a fiscal shock $h$ quarters ago. The top panel of table 11 compares multipliers in this study against those in Blanchard & Perotti (2002) over a five year horizon after a shock to spending. Our multiplier is significant over the 20 quarters, unlike that by Blanchard & Perotti (2002) which fluctuates from being significant in quarter one, insignificant in quarters four to eight and the significant after twelve quarters. Our multiplier converges to 1.62, so our model estimates that a $1 increase in government spending results in a $1.62 increase in GDP. This is in contrast to the 1.29 multiplier that Blanchard & Perotti (2002) finds. However, the Haavelmo multiplier converges to a higher level of 1.77. The balanced budget stimulus generates a higher increase in output - 14 cents more than a purely spending stimulus. Figure (8) is a plot of the two multipliers.

5.1.3 Monetary policy shock

Joint modelling of fiscal policy and monetary policy captures the effects of the actions of one policy maker on economic variables that are of interest to another policy maker: the effect of fiscal policy...
on monetary policy, and vice versa. We have indeed seen above that spending and tax shocks affect the federal funds rate in the long-run, according to equation (21). Monetary policy also affects fiscal variables not just in the short-run but also when the liquidity premium relation affects taxes, for example. These effects are augmented by results from impulse response analysis where there are significant, albeit temporary, changes in tax revenues after a monetary policy shock. For other variable responses, inflation falls temporarily and with a lag. The Treasury yield suffers no significant changes but the corporate bond yield by 31 bps. A falling liquidity premium, and rising real short-term interest rate point to monetary policy’s potency in cooling an over-heating economic activity, at least temporarily. Such an policy is helped by an increase in the risk premium.

6 Conclusion

We have investigated the dynamics of fiscal and monetary policy with respect to their effect on output, inflation, and long-term interest rates. Jointly modelling monetary and fiscal policy allows us to capture the extent of the interaction between the government and the central bank insofar as one’s actions affect the other. This is in addition to the effect of either policy maker’s actions on output, inflation, and long-
run interest rates. In particular, we investigate the Haavelmo shock, the idea that a simultaneous increase in spending and taxes which leaves the deficit unchanged should have a significant effect on output. This is indeed found to be the case based on a balanced budget multiplier of 1.77 that we estimate. A spending only multiplier is found to be 1.62. We find that fiscal policy directly affects monetary policy via the deficit, with the federal funds rate falling in response to an increase in the deficit. The effects of monetary policy tightening are qualitatively in line with findings in the literature with output and inflation falling, while corporate longer maturity bond yields rise. The temporary increase in the risk premium suggests that the corporate bond yield rises faster and by more than the government bond, evidence that the central bank can alter economic conditions by targeting the risk premium. That the Haavelmo shock significantly affects output offers a powerful tool in the use of taxes and spending for economic stabilisation. Such a policy offers a viable compromise between proponents for tax or spending-based stabilisation of the economy.

A Interest rates

We replicate the splicing technique in Krolzig & Sserwanja (2014a) to approximate missing data in the government bond yield series. Data is available for all series from 1960M1 except for the GS30 series which starts in 1977M2. GS30 data is also missing between 2002M3 and 2006M1, during which no new 30-year maturity Treasuries were issued. To match maturity with corporate bonds, splicing is used to approximate the missing data points in the 30-year Treasury series with 20-year Treasuries. Monthly data is used for splicing so as to capture at as close a frequency as possible data details at the start and end dates for which data is missing than would otherwise be possible were quarterly data to be used. Changes in the two yields should be close at lower frequencies. Due to the location of the missing data, the splicing implemented here takes two forms. For the 1959M1 – 1977M2 period, equation (22) is used. Crucially, (22) approximates the month-on-month change in the 30-year Treasury yield by the month-on-month change in the 20-year Treasury yield. Looking at the lower panel in figure 11, this assumption is justifiable. For the period 2002M3 – 2006M1, (23) equates the growth rate in the 30-year Treasury yield to the sum of the growth rate of the 20-year Treasury yield and the difference in the two growth rates over the period data is missing, weighted by the number of periods for which data is missing.

Backward iteration:

\[ GS30_t = GS30_{t+1} - \Delta GS20_{t+1} \]  (22)

Forward iteration:

\[ GS30_t = \Delta GS30_{t-1} + \Delta GS20_t + \Delta t_{t_1-t_0}(GS30_{t_1} - GS20_{t_1}) \]  (23)

The long-term behaviour of the $GS20_t$ and $GS30_t$ series lend credence to the assumption that these two series are linked. Their graphs below confirm this close relationship. Looking at the ranges

27
1977M2 – 1986M12, and 1993M10 – 2002M2 in figure 11 for which both GS20t and GS30t data is available, it is evident that these two series closely track each other. Their first-difference plots in the bottom panel of figure 11 is further support for this argument. The full GS30t series is then transformed to quarterly frequency by evaluating the simple average for the three months making up a quarter for quarters 1-4.
